NL-Augmenter

A Framework for Task-Sensitive Natural Language Augmentation

Abstract Data augmentation is an important method for evaluating the robustness of and enhancing the diversity of training data for natural language processing (NLP) models. In this paper, we present NL-Augmenter, a participatory Python-based natural language (NL) augmentation framework which supports the creation of transformations (modifications to the data) and filters (data splits according to specific features). We describe the framework and an initial set of 117 transformations and 23 filters for a variety of NL tasks annotated with noisy descriptive tags. The transformations incorporate noise, intentional and accidental human mistakes, socio-linguistic variation, semantically-valid style, syntax changes, as well as artificial constructs that are unambiguous to humans. We demonstrate the efficacy of NL-Augmenter by using its transformations to analyze the robustness of popular language models. We find different models to be differently challenged on different tasks, with quasi-systematic score decreases. The infrastructure, datacards, and robustness evaluation results are publicly available on GitHub for the benefit of researchers working on paraphrase generation, robustness analysis, and low-resource NLP.

El aumento de datos es un método importante para evaluar la solidez y mejorar la diversidad del entrenamiento de modelos para procesamiento de lenguaje natural (NLP). En este trabajo, presentamos NL-Augmenter, un nuevo participatorio framework de lenguaje natural (NL) que utiliza el proceso de transformaciones (modificaciones de datos) y filtros (división de datos según características específicas). Describimos el framework y una serie inicial de 117 transformaciones y 23 filtros para una variedad de tareas de NL anotadas con etiquetas descriptivas perturbadas. Las transformaciones incorporan ruido, errores intencionales y accidentales humanos, variación socio-lingüística, estilo semánticamente válido, cambios de sintaxis, así como constructos artificiales que no son ambiguos para humanos. Demostramos la efectividad de NL-Augmenter mediante el uso de sus transformaciones para analizar la robustez de modelos de lenguaje populares. Encontramos diferentes modelos enfrentados de manera diferente a diferentes tareas, con desviaciones de puntuaciones sistemáticas. La infraestructura, tarjetas de datos y resultados de evaluación de robustez están públicamente disponibles en GitHub para el beneficio de los investigadores trabajando en generación de paráfrasis, análisis de robustez y lenguaje de baja resolución.

1 Introduction

Data augmentation, the act of creating new datapoints by slightly modifying copies or creating synthetic data based on existing data, is an important component in the robustness evaluation of models in natural language processing (NLP) and in enhancing the diversity of their training data. Most data augmentation techniques create examples through transformations of existing examples which are based on prior task-specific knowledge (Feng et al., 2021; Chen et al., 2021). Such transformations seek to disrupt model predictions or can be used as training candidates for improving regularization and denoising models, for example through consistency training (Xie et al., 2020). Figure 1 illustrates a number of possible transformations for a sample sentence.

However, the vast majority of transformations do not alter the structure of examples in drastic and meaningful ways, rendering them qualitatively less effective as potential training or test examples. Moreover, different NLP tasks may benefit from transforming different linguistic properties. Changing the word “happy” to “very happy” in an input is more relevant for sentiment analysis than for summarization (Mille et al., 2021). Despite this, many transformations are universally useful, for example changing places to ones from different geographic regions, or changing names to those from different cultures. Hence, a single repository that aggregates both task-specific and task-independent transformations will lower the barrier to entry for creating appropriate augmentation suites for any task.

Another advantage of supporting a broad range of transformations is the ability to capture the long-tailed nature and high diversity of surface forms of natural language (Bamman, 2017). The current paradigm of testing models on data drawn i.i.d. from long-tailed distribution results in the head of the distribution being emphasized even in the test dataset and rare phenomena implicitly ignored by aggregate performance numbers. Researchers have thus argued for more fine-grained breakdowns of results in ways that capture these under-represented groups (Mitchell et al., 2019). However, the identification of these groups depends on and benefits from different cultural backgrounds and expertise. To capture a wide range of backgrounds, we thus capitalize on the “wisdom-of-researchers” and develop NL-Augmenter in a participatory framework.

NL-Augmenter is a Python-based natural language (NL) augmentation framework that aims to enable more diverse and better characterized data during testing and training. Drawing upon researchers from computational linguistics, NLP, and other related fields, we collect 117 different ways to augment data for NL tasks.

To encourage task-specific implementations, we link each transformation to a widely-used data format (e.g. text pair, a question-answer pair, etc.) along with the task types (e.g. entailment, tagging, etc.) that they support. NL-Augmenter also provides more than 23 different filters, which can be used to create input subpopulations, according to features such as input complexity, input size, etc. Unlike a transformation, the output of a filter is a boolean value, indicating whether the input meets the filter criterion, e.g., whether the input text is classified as toxic. We evaluate the robustness of four common pre-trained language models on four different tasks by testing their performance on perturbed test sets. The results demonstrate how NL-Augmenter can easily corroborate prior findings that current pre-trained models are strongly affected by small perturbations in texts. Additionally, we expect NL-Augmenter to be an effective tool for training data augmentation to develop models that are robust to diverse language characteristics.

2 Related Work

Participatory Benchmarks & Wisdom-of-Researchers Addressing the problem of under-resourced African languages in machine translation, Masakhane adopted a participatory approach to construct benchmarks for over thirty languages (Nekoto et al., 2020). Such collaborative approaches are becoming increasingly common (Cahyawijaya et al., 2022) in NLP to keep up with the rapid pace of NLP progress via benefitting from collaboration. The Generation Evaluation and Metrics benchmark (Gehrmann et al., 2021, 2022), which started the development of NL-Augmenter, is a participatory project to document and improve evaluation processes in natural language generation. BIG-Bench is a collaborative framework to collect few-shot tasks that gauge the abilities of large, pretrained language models. DynaBench (Kiela et al., 2021) iteratively evaluates models in a human-in-the-loop fashion by enabling humans to construct challenging examples. SyntaxGym (Gauthier et al., 2020) provides a platform for researchers to contribute and use evaluation sets with a focus on targeted syntactic evaluation of Language Models (LMs), particularly psycho-linguistically motivated ones. The collaboration process for NL-Augmenter is inspired by these projects allowing us to reach for a much broader scope and to collect transformations that operate on a larger variety of tasks and model types. Through our participatory approach, the lived experiences of a diverse group of individuals enable identifying and codifying an extensive list dimensions of variation.

---

1https://github.com/GEM-benchmark/NL-Augmenter

2https://github.com/google/BIG-bench
which are encoded as executable transformations (Tan et al., 2021b). Leveraging the wisdom-of-the-crowd (Galton, 1907; Yi et al., 2010) is common in our field of NLP, often through the use of crowdsourcing platforms like Amazon Mechanical Turk that provide access to many raters, although not representative of the broader population (Fort et al., 2011). To harness the wisdom-of-researchers instead, we follow the example by BIG-bench which is hosted on GitHub and offers co-authorship in exchange for task contribution.

**Robustness Evaluation Tools** There are many projects with similar goals that inspired NL-Augmenter. For example Gardner et al. (2020) create “contrast” sets of perturbed test examples. In their approach, each example is manually perturbed, which may lead to higher-quality results but is costly to replicate for each new task due to scale and annotator cost. TextAttack (Morris et al., 2020) and TextFlint (Wang et al., 2021a) are libraries to conduct adversarial evaluations of English and Chinese models. They cover linguistic and task-specific transformations, adversarial attacks, and subpopulation analyses. In contrast, while the majority of transformations are focused on English, NL-Augmenter supports many more languages and each contribution can specify a set of supported languages.

Robustness Gym (Goel et al., 2021) unifies four different types of robustness tests — subpopulations, transformations, adversarial attacks, and evaluation sets — in a single interface in their released library. While conceptually similar, the design of NL-Augmenter puts an emphasis on modularity to enable a lower barrier of entry for contributors, which is reflected in its size and diversity. Checklist (Ribeiro et al., 2020) argues for the need to go beyond simple accuracy and evaluate the model on basic linguistic capabilities, for example their response to negations. Polyjuice (Wu et al., 2021) perturbs examples using GPT-2 — though this is automatic and scalable, it offers limited control over type of challenging examples generated, making fine-grained analysis beyond global challenge-set level difficult. In contrast, our method offers a richer taxonomy with 117 (and growing) transformations for extensive analysis and comparison.

Tan et al. (2021b) propose decomposing each real world environment into a set of dimensions before using randomly sampled and adversarially optimized transformations to measure the model’s average- and worst-case performance along each dimension. NL-Augmenter can be used, out-of-the-box, to measure average-case performance and we plan to extend it to support worst-case evaluation.

Figure 1: A few randomly chosen transformations of NL-Augmenter for the original sentence *John likes expensive pizzas*. While the meaning (almost) always remains the same and identifiable by humans, models can have a much harder time representing the transformed sentences.
Table 1: Comparison of NL-Augmenter with other data augmentation and robustness evaluation libraries. *These are configurable transformations with multiple child transformations.

3. **NL-Augmenter**

NL-Augmenter is a crowd-sourced suite to facilitate rapid augmentation of data for NLP tasks to assist in training and evaluating models. NL-augmenter was introduced in Mille et al. (2021) in the context of the creation of evaluation suites for the GEM benchmark (Gehrmann et al., 2021, 2022); three types of evaluation sets were proposed: (i) transformations, i.e. original test sets are perturbed in different ways (e.g. back-translation, introduction of typographical errors, etc.), (ii) subpopulations, i.e. test subsets filtered according to features such as input complexity, input size, etc.; and (iii) data shifts, i.e. new test sets that do not contain any of the original test set material.

In this paper, we present a participant-driven repository for creating and testing transformations and filters, and for applying them to all dataset splits (training, development, evaluation) and to all NLP tasks (NLG, labeling, question answering, etc.). As shown by Mille et al. (2021), applying filters and transformations to development/evaluation data splits allows for testing the robustness of models and for identifying possible biases; on the other hand, applying transformations and filters to training data (data augmentation) allows for possibly mitigating the detected robustness and bias issues (Wang et al., 2021b; Pruksachatkun et al., 2021; Si et al., 2021).

A majority of the augmentations that the framework supports are transformations of single sentences that aim to paraphrase these sentences in various ways. NL-Augmenter loosens the definition of “transformations” from the logic-centric view of strict equivalence to the more descriptive view of linguistics, closely resembling Bhagat and Hovy (2013)’s “quasi-paraphrases”. We extend this to accommodate noise, intentional and accidental human mistakes, sociolinguistic variation, semantically-valid style, syntax changes, as well as artificial constructs that are unambiguous to humans (Tan et al., 2021b). Some transformations vary the socio-linguistic perspective permitting a crucial source of variation wherein language goals span beyond conveying ideas and content.

In this section, we provide organizational details, list the transformations and filters that the repository currently contains, and we present the list of tags we associated to transformations and filters and how we introduced them.

### 3.1 Participatory Workshop on GitHub

A workshop was organized towards constructing this full-fledged participant-driven repository. Unlike a traditional workshop wherein people submit papers, participants were asked to submit python implementations of transformations to the GitHub repository. Organizers of this workshop created a base repository extending Mille et al. (2021)’s NLG evaluation suite and incorporated a set of interfaces, each of which catered to popular NL example formats. This formed the backbone of the repository. A sample set of transformations and filters along with evaluation scripts were provided as starter code. Figure 2 shows an annotated code snippet of a submission. Following the format of BIG-Bench’s review process, multiple review criteria were designed for accepting contributions. The review criteria (see Appendix C) guided participants to follow a style guide, incorporate test cases in JSON format, and encouraged novelty and specificity. Apart from the general software development advantages of test cases, they made reviewing simpler by providing an overview of the transformation’s capability and scope of generations.

### 3.2 Review Process

Each participant was expected to follow the review criteria mentioned in Figure 3. Rule-based transformations depending on well-studied lexical resources like WordNet, Wikipedia, PropBank, Implications were almost always selected due to their high precision as well as their ability to offer diverse synonymy. Machine Learning based transformations (e.g. Transformers fine-tuned on paraphrase datasets) were encour-
aged if they included either previously reported or newly measured metrics. ML-based transformations based on previously published work were thus also accepted. Duplicate submissions were rejected.

Figure 2: Participants were expected to write their python class adhering to the above format.

Those transformations which resulted in immeasurable meaning change or untracked label changes were rejected. During the peer review, reviewers examined example outputs to decide whether a transformation had immeasurable meaning change. Reviewers were asked to instigate constructive discussions and suggest improvements to the code and the transformations. As each transformation was paired with at least 2 reviewers and the submissions were discussed publicly, most of these transformations had to improve & resubmit modified versions. The discussions between reviewers and participants leading up acceptances or rejections are available publicly to encourage transparency and reproducibility as well as foster ancillary projects.

Since reviewers were the main guarantors of quality, it was imperative to provide a fair and qualitative review to participants and hence submissions were scrutinised by both participants as well as the organizers. From our initial advertising on relevant mailing lists and personally emailing authors of the relevant papers (i.e. papers focused on paraphrasing, augmentation, adversarial learning and robustness analysis) helped us in obtaining a diverse pool of volunteers. The reviewers were affiliated to about 90 organisations during the course of review out of which approximately two-thirds were academic and the rest were industrial in nature. To ensure that the submissions adhere to the larger goals of the project we let organizers have the final say of acceptance, much like meta-reviewers in conferences.

3.3 Transformations and filters

We received a total of 170 submissions out of which 117 transformations and 23 filters were accepted and merged. They have been listed in Tables 2 and 3 respectively (and alphabetically ordered according to the submission name in the repository). For each transformation/filter, a link to the corresponding Appendix subsection is provided, where a detailed description, illustrations and an external link to the implementation in the NL-Augmenter repository can be found.

3.4 Tags for the classification of perturbations

We defined a list of tags which are useful for an efficient navigation in the pool of existing perturbations and for understanding the performance characteristics of the contributed transformations and filters (see e.g. the robustness analysis presented in Section 7). There are three main categories of tags: (i) General properties tags, (ii) Output properties tags, and (iii) Processing properties tags.

General properties tags are shown in Table 4, and cover the type of the augmentation, i.e. whether it is a transformation or a filter (Augmented set type), its general purpose, i.e. whether it is intended for augmentation, robustness, etc. (General purpose), for which NLP tasks the created data will be useful (Task type), to which languages it has been applied (Language(s)), and on which linguistic level of representation it operates, i.e. semantic, syntactic, lexical, etc. (Linguistic level).

Output properties tags, shown in Table 5, apply to transformations only; they provide indications about how the data was affected during the respective transformations. There are currently six properties in this category: one to capture the number of different outputs that a transformation can produce (Output/Input ratio), one to capture in which aspect the input and the output are alike (Input/Ouput similarity), and four to capture intrinsic qualities of the produced text or structured data, namely how were the meaning, the grammaticality, the readability and the naturalness affected by the transformation (respectively Meaning preservation, Grammaticality preservation, Readability preservation and Naturalness preservation). Note that apart from Output/Input ratio, the output properties tags need to be specified manually for each transformation/filter (see Section 3.5), and are thus subject to the interpretation of the annotator.

---

Some submissions also received up to 5-6 reviews.

Processing properties tags, shown in Table 6, capture information related to the type of processing applied on the input (Input data processing), the type of algorithm used (Algorithm type), how it is implemented (Implementation), its estimated precision and recall (Precision/recall) and computational complexity (Computational complexity / Time), and whether an accelerator is required to apply the transformation/filter (GPU required?).

3.5 Tag retrieval and assignment

Transformation and filters are assigned tags for each of the properties listed in Tables 4-6. There are two sources for the tags: (i) assigning them manually, and (ii) using existing metadata embedded in the respective source code implementations of each given transformation and filter. The in-code metadata (see e.g. the Keywords field in Figure 2) provides descriptions for each one identifiable aspects such as the language(s) supported, the type of task that the transformation or filter is applicable for, and other characteristical keywords. The specification and type of this metadata was predefined as a requirement for all contributors to the NLAugmenter project to enable identification of the type of transformation of filter being written by their respective author(s).

Having a language tag as shown in the sample transformation in Figure 2 separately was crucial to emphasize and encourage multi-lingual transformations and filters.

This metadata was initially collected through the creation of an automated script which programmatically iterated through each transformation and filter and gathered all stated metadata. The metadata was then mapped by the script into discrete property groups as defined in Tables 4-6. All contributing authors were invited to review the initially collected metadata and, where possible, add additional data.

### 4 Robustness Analysis

All authors of the accepted perturbations were asked to provide the task performance scores for each of their respective transformations or filters. In Section 4.1 we provide details on how the scores were obtained, and in Section 7 we provide a first analysis of these scores.

### 4.1 Experiment

The perturbations are currently split into three groups, according to the task(s) they will be evaluated on: text classification tasks, tagging tasks, and question-answering tasks. For experiments we focus on text classification and its relevant perturbations. We compare the models’ performance on the original test data and on the perturbed data. The percentage of sentences be-
ing changed by a transformation (transformation rate) and the percentage of performance drop on the perturbed data compared to the performance on the original data (score variation) are reported.

**Tasks.** We choose four evaluation datasets among three English NLP tasks: (1) sentiment analysis on both short sentences (SST-2 (Socher et al., 2013)) and full paragraphs (IMDB Movie Review (Maas et al., 2011)), (2) Duplicate question detection (QQP) (Wang et al., 2019a), and (3) Natural Language Inference (MNLI) (Williams et al., 2017). These tasks cover both classifications on single sentences, as well as pairwise comparisons, and have been widely used in various counterfactual analysis and augmentation experiments (Wu et al., 2021; Kaushik et al., 2019; Gardner et al., 2020; Ribeiro et al., 2020).

**Evaluation models.** We represent each dataset/task with its corresponding most downloaded large model hosted on Huggingface (Wolf et al., 2020), resulting in four models for evaluation: roberta-base-SST-2, roberta-base-imdb, roberta-large-mnli, and bert-base-uncased-QQP.

**Perturbation strategy.** For each task, we perturb a random sample of 20% of the validation set. Since all the transformations are on single text snippets, for datasets with sentence pairs, i.e., QQP and MNLI, we perturb the first question and the premise sentence, respectively.

### 4.2 Results and Analysis

In this section, Tables 7 to 17 show the results of the robustness analysis performed on the four datasets described in Section 4.1 and presented according to the tags introduced in Section 3.4. As we will see further, many of the tags relay interesting qualitative assessments while in some cases there is no direct correlation.

**General purpose (Table 7):** Transformations designed with a “robustness testing” objective displayed mean performance drops between 9% and 13.7% across models. Interestingly, 34 sentence transformations designed for “augmentation” tasks showed similar mean robustness drops ranging between 4% and 13%, emphasizing the need to draw on the paraphrasing literature to improve robustness testing.

**Task type (Table 8):** The results table shows that there is not necessarily a correlation between which task a transformation is marked to be relevant for and which task it actually challenges the robustness of the models on.

**Linguistic level (Table 9):** Transformations making character level and morphological changes were able to show drastic decreases in the level of performance compared to those making lexical or syntactic changes. These drops in performance were consistent across all four models. roberta-large finetuned on the MNLI dataset was the most brittle - character-level transformations on an average dropped performance by over 31% and morphological changes dropped it by 28% while those which made lexical changes displayed a mean drop of 4.4%. The visual_attack_letters (A.111) transformation, which replaces characters with similarly looking ones (like y and v), shows a large accuracy drop from 94% to 56% on the ‘roberta-base’ model fine tuned on SST. ‘bert-base-uncased’ fine-tuned on the QQP dataset drops from 92 to 69. roberta-large-mnli drops from 91 to 47. In the case of visual_attack_letters, one can easily conceive a scenario in which a model is applied to OCR text which likely exhibit similar properties. In this case, one may expect similarly poor performance, arguably attributed to a narrow set of characters that the models have been exposed to. This drop could potentially be alleviated by adversarial training. As is shown in previous work (Si et al., 2021), training on augmented data improves the performance on the test set with same perturbations.

**Meaning preservation (Table 11):** 22 transformations which were marked as highly meaning preserving surprisingly showed a larger average performance drop as compared to 20 of those which were marked as possibly meaning changing. Not discounting the possibility of the nosiness of the transformation’s logic, we believe further investigation could help understand whether models focus on the meaning of words or sentences or take shortcuts by focusing on commonly occurring surface forms associated with a particular prediction, as was already shown for some phenomena by McCoy et al. (2019), among others.

**Grammaticality preservation (Table 12):** Preserving grammaticality did not correlate with high robustness. Transformations marked as grammaticality always-preserved showed significant average drops of 10.6%, 8.1% and 4.6% across roberta-base-SST-2, roberta-large-mnli and bert-base-uncased-QQP respectively. For example, the grapheme_to_phoneme transformation showed drastic drops in performance: 13%, 20% and 13% respectively.

**Readability and Naturalness (Tables 13-14):** In general, as expected, the transformations tagged as modifying the readability or naturalness show large drops across all tasks and models, in particular the ones tagged as “always impairing” the input.

Unsurprisingly, many of the injected perturbations, despite being artificial would not distract human readers from the actual meaning and intent of the text (e.g. simple_ciphers transformation (A.91)). Character level perturbations might not distract human readers as much as compared to word level perturbations but the above language models on the other hand behaved contrarily. Such departure from learning mean-
The large drops in performance of such perturbations necessitate looking at expanding training sets with even artificial data sources as well expand our definitions of text similarity from pure linguistic ones to those which abstract morphological, visual and other errors which can be unambiguous to humans.

Tables 10, 15, 16 and 17 show the robustness scores for Input/Output similarity, Input processing, Implementation and Algorithm type respectively. The score drops for these criteria may not be easily interpretable; e.g. that model-based implementations showed comparatively larger average drops as compared to rule-based implementations may not be due to the difference in implementation, but rather to which transformations were implemented that way.

5 Discussion and Broader Impact

Limitations In Section 7, we analyze the results of applying some of the transformations on existing datasets and running models on the perturbed data. Even though it was not possible to test all of the currently existing perturbations due to time constraints, the overall results show that the tested perturbations do pose a challenge to different models on different tasks, with quasi-systematic score drops. However, with so many transformations applied to four different datasets, the presented robustness analysis can only be shallow, and a separate analysis of each transformation would be needed in order to get more informative insights. Second, our superficial analysis above relies on tags which were in many cases annotated by hand, and some of the surprising results (e.g. meaning-preserving are more challenging than non-meaning-preserving transformations) may reflect a lack of consistency in the annotations. We believe that assessing the quality of the tag assignment so as to ensure a high inter-annotator agreement will be needed for reliable analyses in the future. Finally, the current robustness analysis only shows that the perturbations are effective for detecting a possible weakness in a model; further experiments are needed to demonstrate that the perturbations can also help mitigating the weaknesses they bring to light.

Dilution of Contributions While this is not our intent, there is a risk in large scale collections of work like this that individual contributions are being less appreciated than releasing them as a standalone project. This risk is a tradeoff with the advantage that it becomes much easier to switch between different transformations, which can lead to a better adoption of introduced methods. To proactively give appropriate credit, each transformation has a data card in the form of a standard README file mentioning the contributors and all participants are listed as co-authors of this paper. We further encourage all users of our repository to cite the work that a specific implementation builds on, if appropriate. The relevant citations are listed on the respective data cards and in the description in the appendix. In the same vein, there is a risk of NL-Augmenter as a whole to monopolize the augmentation space due to its large scope, leading to less usage of related work which may cover additional transformations or filters. While this is not our intention and we actively worked with contributors to related repositories to integrate their work, we encourage researchers to try other solutions as well.

Participatory Setup Conducting research in environments with a shared mission, a low barrier of entry, and directly involving affected communities was popularized by Nekoto et al. (2020). This kind of participatory work has many advantages, most notably that it changes the typically prescriptive research workflow toward a more inclusive one. Another advantage is that through open science, anyone can help shape the overall mission and improve the end result. Following the related BIG-bench(Srivastava et al., 2022) project, we aimed to design NL-Augmenter in a similar spirit – by providing the infrastructure, the participation barrier is reduced to filling a templated interface and providing test example. By making the interface as flexible as possible, the contributions range from filters for subpopulations with specific protected attributes to transformations via neural style transfer. Through this wide range, we hope that researchers can apply a wider range of augmentation and evaluations strategies to their data and models.

6 Conclusion

In this paper, we introduced NL-Augmenter, a framework for text transformations and filters with the goal of assisting in robustness testing and data augmentation tasks. We demonstrated that through an open participation strategy, NL-Augmenter can cover a substantially wider set of languages, tasks, transformations, and filters than existing work, without a loss of focus. Our repository provides >117 transformations and >23 filters that have been documented and tested. We used these transformations to conduct robustness evaluations of popular transformer-based models and found that they are not robust, even to randomly (i.e.,
non-adversarially) sampled perturbations. Although our analyses have revealed some aspects in which NL-Augmenter can be improved, we showed how it can be beneficial to efforts in evaluating the robustness of NLP models. NL-Augmenter can serve as a crucial resource for data augmentation especially for low-resource domains and task-specific language processing. We welcome future contributions to improve its coverage of the augmentation space and to address its current shortcomings. Investigating the effect on model robustness with larger-scale experiments is a potential direction for future work.

7 Organization

NL-Augmenter is an effort organized by researchers and developers ranging across different niches of NLP. To acknowledge everyones contributions, we list the contribution statements below for all.

Steering Committee: Kaustubh Dhole, Varun Gangan, Sebastian Gehrmann, Aadesh Gupta, Zhenhao Li, Saad Mahmoud, Simon Mille, Jascha Sohl-Dickstein, Ashish Shrivastava, Samson Tan, Tongshuang Wu and Abinaya Mahendiran make up the steering committee. Jinho Choi, Eduard Hovy & Sebastian Ruder provided guidance and feedback. Kaustubh Dhole coordinates and leads the NL-Augmenter effort. All others provide feedback and discuss larger decisions regarding the direction of NL-Augmenter and act as organizers and reviewers.

Repository: Kaustubh, Aadesh, Zhenhao, Tongshuang, Ashish, Saad, Varun & Abinaya created the interfaces and the base repository NL-Augmenter for participants to contribute. This was also a continuation of the repository developed for creating challenge sets (Mille et al., 2021) for GEM (Gehrmann et al., 2021). All the other authors expanded this repository with their implementations.

Reviewers: Kaustubh, Simon, Zhenhao, Sebastian, Varun, Samson, Abinaya, Saad, Tongshuang, Aadesh, Ondrej were involved in reviewing the submissions of participants of the first phase. In the 2nd phase, all other authors performed a cross-review, in which participants were paired with 3 other participants. This was followed by a meta review by the organizers.

Robustness Evaluation: Ashish, Tongshuang, Kaustubh & Zhenhao created the evaluation engine. Simon, Kaustubh, Saad, Abinaya & Tongshuang performed the robustness analysis.

Website: Aadesh and Sebastian created the webpages for the project.

The abstract has been written in English, Spanish, Hindi, Chinese, Persian, Quechua, and Indonesian.

A Transformations

The following is the list of all accepted transformations to NL-Augmenter project. Many of the transformations tokenize the sentences using SpaCy\(^4\) or NLTK (Bird, 2006) tokenizers. We discuss the implementations of each along with their limitations. The title of each transformation subsection is clickable and redirects to the actual python implementation. Many of the transformations use external libraries and we urge readers to look at each implementation and its corresponding 'requirements.txt' files.

\(^4\)https://spacy.io/
A.1 Abbreviation Transformation

This transformation replaces a word or phrase with its abbreviated counterpart “homework” → “hwk” using a web-scraped slang dictionary.

You - yu driving at 80 miles per hour - mph is why insurance is - tis so freaking - friggin expensive.

A.2 Add Hash-Tags

This transformation uses words in the text to generate hashtags. These hashtags are then appended to the original text. Using the same words appearing in the sentence to generate the hashtags acts as redundant noise that models should learn to ignore. Hashtags are widespread in social media channels and are used to draw attention to the source text and also as a quick stylistic device.

I love domino’s pizza. - #LovePizza #Love #I #Pizza

A.3 Adjectives Antonyms Switch

This transformation switches English adjectives in a sentence with their WordNet (Miller, 1998) antonyms to generate new sentences with possibly different meanings and can be useful for tasks like Paraphrase Detection, Paraphrase Generation, Semantic Similarity, and Recognizing Textual Entailment.

Amanda’s mother was very beautiful - ugly.

A.4 AmericanizeBritishizeEnglish

This transformation takes a sentence and tries to convert it from British English to American English and vice-versa. A select set of words have been taken from hyperreality@GitHub.

I love the pastel colours - colors

A.5 AntonymsSubstitute

This transformation introduces semantic diversity by replacing an even number of adjective/adverb antonyms in a given text. We assume that an even number of antonyms transforms will revert back sentence semantics; however, an odd number of transforms will revert the semantics. Thus, our transform only applies to the sentence that has an even number of revertible adjectives or adverbs. We called this mechanism double negation.

Steve is able - unable to recommend movies that depicts the lives of beautiful - ugly minds.

A.6 Auxiliary Negation Removal

This is a low-coverage transformation which targets sentences that contain negations. It removes negations in English auxillaries and attempts to generate new sentences with the opposite meaning.

Ujjal Dev Dosanjh was not - Ujjal Dev Dosanjh was the 1st Premier of British Columbia from 1871 to 1872.

A.7 AzertyQwertyCharsSwap

Preferably use the above download link, as the release tarballs are generated deterministically - qre generqted deterministically whereas GitHub’s are not.

A.8 BackTranslation

This transformation translates a given English sentence into German and back to English. This transformation acts like a light paraphraser. Multiple variations can be easily created via changing parameters like the language as well as the translation models which are available in plenty. Backtranslation has been quite popular now and has been a quick way to augment examples (Li and Specia, 2019; Sugiyama and Yoshinaga, 2019).

A.9 BackTranslation for Named Entity Recognition

This transformation splits the token sequences into segments of entity mention(s) and “contexts” around the entity mention(s). Backtranslation is used to paraphrase the contexts around the entity mention(s), thus resulting in a different surface form from the original token sequence. The resultant tokens are also assigned new tags. Exploiting this transformation has shown to empirically benefit named entity tagging (Yaseen and Langer, 2021) and hence could arguably benefit other low-resource tagging tasks (Bhatt and Dhole, 2020; Khachatrian et al., 2019; Gupta et al., 2021).

A.10 Butter Fingers Perturbation

This perturbation adds noise to all types of text sources (sentence, paragraph, etc.) proportional to noise erupting from keyboard typos making common spelling errors. Few letters picked at random are replaced with letters which are at keyboard positions near the source letter. The implementation has been borrowed from here (Yorke) as used in (Mille et al., 2021). There has

---

1 Scraped from https://www.noslang.com/dictionary
also been some recent work in NoiseQA (Ravichander et al., 2021) to mimic keyboard typos.

\textbf{Sentences - Sentences} with gapping, such as Paul likes \textit{coffee} - \textit{coffwe} and Mary tea, lack an overt predicate to indicate -\textit{indicate}x the relation -\textit{relauion} between two or more \textit{arguments} - \textit{argumentd}.

\section{A.11 Butter Fingers Perturbation For Indian Languages}

This implements the butter fingers perturbation as used above for 7 Indian languages: Bangla, Gujarati, Hindi, Kannada, Malayalam, Oriya, Punjabi, Tamil, and Telugu. The implementation considers the InScript keyboard \footnote{https://en.wikipedia.org/wiki/InScript_keyboard} which is decreed as a standard for Indian scripts.

\section{A.12 Change Character Case}

This transformation acts like a perturbation and randomly swaps the casing of some of the letters. The transformation’s outputs will not work with uncased models or languages without casing.

\textit{Alice in Wonderland} is a 2010 American live-\textit{action} - \textit{action/animated} - \textit{animated} dark \textit{fantasy} - \textit{faNtasy} adventure film.

\section{A.13 Change Date Format}

This transformation changes the format of dates.

The first known case of COVID-19 was identified in Wuhan, China in December - Dec 2019.

\section{A.14 Change Person Named Entities}

This perturbation changes the name of the person from one name to another by making use of the lexicon of person names in Ribeiro et al. (2020).

\textit{Andrew} - \textit{Nathaniel} finally returned the French book to Chris that I bought last week.

\section{A.15 Change Two Way Named Entities}

This perturbation also changes the name of the person but also makes a parallel change in the label or reference text with the same name making it useful for text-to-text generation tasks.

He finally returned the French book to \textit{Chris} - \textit{Austin} that I bought last week.

\section{A.16 Chinese Antonym and Synonym Substitution}

This transformation substitutes Chinese words with their synonyms or antonyms by using the Chinese dictionary\footnote{Chinese Dictionary: https://github.com/guotong1988/chinese_dictionary} and NLP Chinese Data Augmentation dictionary\footnote{NLP Chinese Data Augmentation: https://github.com/425776824/nlpcha}.

\section{A.17 Chinese Pinyin Butter Fingers Perturbation}

This transformation implements the Butter Fingers Perturbation for Chinese characters. Few Chinese words and characters that are picked at random will be substituted with others that have similar pinyin (based on the default Pinyin keyboards in Windows and Mac OS). It uses a database of 16142 Chinese characters \footnote{https://github.com/pwxcoo/chinese-xinhua} and its associated pinyin to generate the perturbations for Chinese characters. A smaller database of 3500 \footnote{https://github.com/elephantnose/characters} more frequently seen Chinese characters are also used in the perturbations with a higher probability of being used compared to less frequently seen Chinese characters. It also uses a database of 575173 words \footnote{http://thuocl.thunlp.org/} that are combined from several sources \footnote{https://github.com/fighting41love/Chinese_from_dongxiexidian} in order to generate perturbations for Chinese words.

\section{A.18 Chinese Person Named Entities and Gender Perturbation}

This perturbation adds noise to all types of text sources containing Chinese names (sentence, paragraph, etc.) by swapping a Chinese name with another Chinese name whilst also allowing the possibility of gender swap. CLUENER (Xu et al., 2020; Zhao et al., 2019) is used for tagging named entities in Chinese. The list of names is taken from the Chinese Names Corpus! (Yunfei). It can provide assistance in detecting biases present in language models and the ability to infer implicit gender information when presented with gender-specific names. This can also be useful in mitigating representation biases in the input text.

\section{A.19 Chinese (Simplified & Traditional) Perturbation}

This perturbation adds noise to all types of text sources containing Chinese words and characters (sentence,
paragraph, etc.) by changing the words and characters between Simplified and Traditional Chinese as well as other variants of Chinese Characters such as Japanese Kanji, character-level and phrase-level conversion, character variant conversion and regional idioms among Mainland China, Taiwan and Hong Kong, all available as configurations originally in the OpenChineseConvert project.

A.20 City Names Transformation

This transformation replaces instances of populous and well-known cities in Spanish and English sentences with instances of less populous and less well-known cities to help reveal demographic biases (Mishra et al., 2020) prevalent in named entity recognition models. The choice of cities have been taken from the World Cities Dataset.

The team was established in Dallas - Viera West in 1898 and was a charter member of the NFL in 1920.

A.21 Close Homophones Swap

Humans are generally guided by their senses and are unconsciously robust against phonetic attacks. Such types of attacks are highly popular in languages like English which has an irregular mapping between pronunciation and spelling (Eger and Benz, 2020). This transformation mimics writing behaviors where users swap words with similar homophones either intentionally or by accident. This transformation acts like a perturbation to test robustness. Few words picked at random are replaced with words with similar homophones which sound similar or look similar. Some of the word choices might not be completely natural to normal human behavior, since humans “prefer” some words over others even they sound exactly the same. So it might not be fully reflecting the natural distribution of intentional or unintentional swapping of words.

Sentences with gapping, such as Paul likes coffee and Mary tea - Tee, lack an overt predicate to indicate the - Thee relation between two or more - Morr arguments.

A.22 Color Transformation

This transformation augments the input sentence by randomly replacing mentioned colors with different ones from the 147 extended color keywords specified by the World Wide Web Consortium (W3C). Some of the colors include “dark sea green”, “misty rose”, “burly wood”.

Tom bought 3 apples, 1 orange - misty rose , and 4 bananas and paid $10.

A.23 Concatenate Two Random Sentences (Bilingual)

Given a dataset, this transformation concatenates a sentence with a previously occurring sentence as explained in (Nguyen et al., 2021). A monolingual version is mentioned in the subsequent subsection below. This concatenation would benefit all text tasks that use a transformer (and likely other sequence-to-sequence architectures). Previously published work (Nguyen et al., 2021) has shown a large gain in performance of low-resource machine translation using this method. In particular, the learned model is stronger due to being able to see training data that has context diversity, length diversity, and (to a lesser extent) position shifting.

A.24 Concatenate Two Random Sentences (Monolingual)

This is the monolingual counterpart of the above.

I am just generating a very very very long sentence to make sure that the method is able to handle it. It does not even need to be a sentence. Right? This is not splitting on punctuation... I am just generating a very very very long sentence to make sure that the method is able to handle it. It does not even need to be a sentence. Right? This is not splitting on punctuation...

A.25 Concept2Sentence

This transformation intakes a sentence, its associated integer label, and (optionally) a dataset name that is supported by huggingface/datasets (Lhoest et al., 2021a,b). It works by extracting keyword concepts from the original sentence, passing them into a BART (Lewis et al., 2020) transformer trained on CommonGen (Lin et al., 2019) to generate a new, related sentence which reflects the extracted concepts. Providing a dataset allows the function to use transformers-interpret (Pierse, 2021) to identify the most critical concepts for use in the generative step. Underneath the hood, this transform makes use of the Sibyl tool (Harel-Canada, 2021), which is capable of also transforming the label as well. However, this particular implementation of C2S generates new text that is invariant (INV) with respect to the label. Since the model is trained on CommonGen, which is focussed on image captioning, the style of the...
output sentence would be geared towards scenic descriptions and might not necessarily adhere to the syntax of the original sentence. Besides, it can be hard to argue that a handful subset of keywords could provide a complete description of the original sentence.

A.26 Contextual Meaning Perturbation

This transformation was designed to model the "Chinese Whispers" or "Telephone" children’s game: The transformed sentence appears fluent and somewhat logical, but the meaning of the original sentence might not be preserved. To achieve logical coherence, a pre-trained language model is used to replace words with alternatives that match the context of the sentence. Grammar mistakes are reduced by limiting the type of words considered for changes (based on POS tagging) and replacing adjectives with adjectives, nouns with nouns, etc. where possible.

This transformation benefits users who seek perturbations that preserve fluency but not the meaning of the sentence. For instance, it can be used in scenarios where the meaning is relevant to the task, but the model shows a tendency to over-rely on simpler features such as the grammatical correctness and general coherence of the sentence. A real-world example would be the training of quality estimation models for machine translation (does the translation maintain the meaning of the source?) or for text summarisation (does the summary capture the content of the source?).

Word substitution with pre-trained language models has been explored in different settings. For example, the augmentation library nlpaug (Ma, 2019) and the adversarial attack library TextAttack (Morris et al., 2020) include contextual perturbation methods. However, their implementations do not offer control over the type of words that should be perturbed and introduce a large number of grammar mistakes. If the aim is to change the sentence’s meaning while preserving its fluency, this transformation can help to get the same effect with significantly fewer grammatical errors. Li et al. (2020a) propose an alternative approach to achieve a similar objective.

A.27 Contractions and Expansions Perturbation

This perturbation substitutes the text with popular expansions and contractions, e.g., “I’m” is changed to “I am” and vice versa. The list of commonly used contractions & expansions and the implementation of perturbation has been taken from Checklist (Ribeiro et al., 2020).

He often does n’t - not come to school.

A.28 Correct Common Misspellings

This transformation acts like a lightweight spell-checker and corrects common misspellings appearing in text by looking for words in Wikipedia’s Lists of Common Misspellings.

Andrew andd - and Alice finally returnd - returned the French book that I bought lastr - last week

A.29 Country/State Abbreviation

This transformation replaces country and state names with their common abbreviations. Abbreviations can be common across different locations: “MH” can refer to Country Meath in Ireland as well as the state of Maharashtra in India and hence this transformation might result in a slight loss of information, especially if the surrounding context doesn’t have enough signals.

One health officer and one epidemiologist have boarded the ship in San Diego, CA - California on April 13, 2015 to conduct an environmental health assessment.

A.30 Decontextualisation of the main Event

Semantic Role Labelling (SRL) is a powerful shallow semantic representation to determine who did what to whom, when, and where (and why and how etc.). The core arguments generally talk about the participants involved in the event. Additionally, contextual arguments on the other hand provide more specific information about the event. After tagging a sentence with an appropriate semantic role labels using an SRL labeller (Jindal et al., 2020; Shi and Lin, 2019a). This transformation crops out contextual arguments to create a new sentence with a minimal description of the event. Helping to generate textual pairs for entailment.

A.31 Diacritic Removal

“Diacritics are marks placed above or below (or sometimes next to) a letter in a word to indicate a particular pronunciation in regard to accent, tone, or stress as well as meaning, especially when a homograph exists without the marked letter or letters.” Merriam-Webster. This transformation removes these diacritics or accented characters, and replaces them with their non-accented versions. It can be common for non-native or inexperienced speakers to miss out on any accents and specify non-accented versions.

16Countries States Cities Database: https://github.com/dr5hn/countries-states-cities-database
She looked east and she looked west.

A.32 Disability/Differently Abled Transformation
Disrespectful language can make people feel excluded and represent an obstacle towards their full participation in the society (Res, 2006). This low-coverage transformation substitutes outdated references to references of disabilities with more appropriate and respectful ones which avoid negative connotations. A small list of inclusive words and phrases have been taken from a public article on inclusive communication, Wikipedia’s list of disability-related terms with negative connotations, terms to avoid while writing about disability.

They are deaf - person or people with a hearing disability.

A.33 Discourse Marker Substitution
This perturbation replaces a discourse marker in a sentence by a semantically equivalent marker. Previous work has identified discourse markers that have low ambiguity (Pitler et al., 2008). This transformation uses the corpus analysis on PDTB 2.0 (Prasad et al., 2008) to identify discourse markers that are associated with a discourse relation with a chance of at least 0.5. Then, a marker is replaced with a different marker that is associated to the same semantic class.

It has plunged 13% since inasmuch as July to around 26 cents a pound. A year ago ethylene sold for 33 cents.

A.34 Diverse Paraphrase Generation Using SubModular Optimization and Diverse Beam Search
This transformation generates multiple paraphrases of a sentence by employing 4 candidate selection methods on top of a base set of backtranslation models. 1) DiPS (Kumar et al., 2019) 2) Diverse Beam Search (Vijayakumar et al., 2018) 3) Beam Search (Wiseman and Rush, 2016) 4) Random. Unlike beam search which generally focusses on the top-k candidates, DiPS introduces a novel formulation of using submodular optimisation to focus on generating more diverse paraphrases and has been proven to be an effective data augmenter for tasks like intent recognition and paraphrase detection (Kumar et al., 2019). Diverse Beam Search attempts to generate diverse sequences by employing a diversity promoting alternative to the classical beam search (Wiseman and Rush, 2016).

A.35 Dislexia Words Swap
This transformation acts like a perturbation by altering some words of the sentences with abberations (Board, 2021) that are likely to happen in the context of dyslexia.

Biden hails your - you're relationship with Australia just days after new partnership drew ire from France.

A.36 Emoji Icon Transformation
This transformation converts emojis into their equivalent keyboard format (e.g., 😂 -> :”) and vice versa (e.g., “)” -> 😂).

A.37 Emojify
This transformation augments the input sentence by swapping words with emojis of similar meanings. Emojis, introduced in 1997 as a set of pictograms used in digital messaging, have become deeply integrated into our daily communication. More than 10% of tweets17 and more than 35% of Instagram posts18 include one or more emojis in 2015. Given the ubiquitouness of emojis, there is a growing body of work researching the linguistic and cultural aspects of emojis (Guntuku et al., 2019) and how we can leverage the use of emojis to help solve NLP tasks (Eisner et al., 2016).

Apple is looking at buying U.K. startup for $132 billion. - is at startup for $.

A.38 English Inflectional Variation
This transformation adds inflectional variation to English words and can be used to test the robustness of models against inflectional variations. In English, each inflection generally maps to a Part-Of-Speech tag19 in the Penn Treebank (Marcus et al., 1993). For each content word in the sentence, it first lemmatised before randomly sampling a valid POS category and reflecting the word according to the new category. The sampling process for each word is constrained using its POS tag to maintain the original sense for polysemous words. This has been adapted from the Morpheus (Tan et al., 2020) adverserial attack.

Ujjal Dev Dosanjh served - serve as 33rd Premier - Premiers of British Columbia from 2000 to 2001.

18https://instagram-engineering.com/
19Penn TreeBank POS
A.39 English Mention Replacement for NER

This transformation randomly swaps an entity mention with another entity mention of the same entity type. Exploiting this transformation as a data augmentation strategy has been empirically shown to improve the performance of underlying (NER) models (Dai and Adel, 2020).

A.40 Filler Word Augmentation

This augmentation adds noise in the form of colloquial filler phrases. 23 different phrases are chosen across 3 different categories: general filler words and phrases (“uhm”, “err”, “actually”, “like”, “you know”...), phrases emphasizing speaker opinion/mental state (“I think/believe/mean”, “I would say”...) & phrases indicating uncertainty (“maybe”, “perhaps”, “probably”, “possibly”, “most likely”). The latter two categories had shown promising results Kovatchev et al. (2021) when they were concatenated at the beginning of the sentence unlike this implementation which perform insertions at any random positions. Filler words are based on the work of Laserna et al. (2014) but have not been explored in the context of data augmentation.

A.41 Style Transfer from Informal to Formal

This transformation transfers the style of text from formal to informal and vice versa. It uses the implementation of Styleformer (Damodaran).

What you currently doing ?

A.42 French Conjugation Substitution

This transformation change the conjugation of verbs for simple french sentences with a specified tense. It detects the pronouns used in the sentence in order to conjugate accordingly whenever a sentence contains different verbs. This version only works for indicative tenses. It also only works for simple direct sentences (subject, verb, COD/COI), which contains a pronoun as subject (il, elle, je etc.). It does not detect when the subject is a couple of nouns (“les enfants” or “la jeune femme”).

A.43 Gender And Culture Diversity Name Changer (1-way and 2-way)

Corpora exhibits many representational biases and this transformation focuses on one particular mediator, the personal names. It diversifies names in the corpora along two critical dimensions, gender and cultural background. Technically, the transformation samples a (country, gender) pair and then randomly draws a name from that (country, gender) pair to replace the original name. We collected 42812 distinct names from 141 countries. They are primarily from the World Gender Name Dictionary (Raffo, 2021).

Common name augmentations do not consider their gender and cultural implication. Thus, they do not necessarily mitigate biases or promote the minority’s representation because the augmented name may be from the same gender and cultural background. This is the case, for example in the CheckList’s (Ribeiro et al., 2020) implemented name augmentation. Taking the interaction of the names therein with ours, 34.0%, 33.5%, 31.9%, 30.8% of them are popular names in US, Canada, Australia, and UK, respectively. Only 0.4%, 0.4%, 0.5%, 2.1% of them are from India, Korea, China, and Kazakhstan.

Rachel - Charity Green, a sheltered but friendly woman, flees her wedding day and wealthy yet unfulfilling life.

A.44 Neopronoun Substitution

This transformation performs grammatically correct substitution from English to English of the gendered pronouns, he/she, in a given sentence with their neopronoun counterparts, based on a list compiled by UNC Greensboro and LGBTA WIKI. NLP models, such as those for neural machine translation, often fail to recognize the neopronouns and treat them as proper nouns. This transformation seeks to render the training data used in NLP pipelines more neopronoun aware to reduce the risk of trans-erasure. The reason why a simple look-up-table approach might not work is due to the fact that the case may differ depending on the context.

She - They had her - their friends tell her - them about the event.

A.45 Gender Neutral Rewrite

This transformation involves rewriting an English sentence containing a single gendered entity with its gender-neutral variant. One application is machine translation, when translating from a language with gender-neutral pronouns (e.g. Turkish) to a language with gendered pronouns (e.g. English). This transformation is based on the algorithm proposed by Sun et al. (2021).

His - Their dream is to be a firefighter when he - they grows - grow up.

A.46 GenderSwapper
This transformation introduces gender diversity to the given data. If used as data augmentation for training, the transformation might mitigate gender bias, as shown in Dinan et al. (2020). It also might be used to create a gender-balanced evaluation dataset to expose the gender bias of pre-trained models. This transformation performs lexical substitution of the opposite gender. The list of gender pairs (shepherd <-> shepherdess) is taken from Lu et al. (2019). Genderwise names used from Ribeiro et al. (2020) are also randomly swapped.

A.47 GeoNames Transformation
This transformation augments the input sentence with information based on location entities (specifically cities and countries) available in the GeoNames database. E.g., if a country name is found, the name of the country is appended with information about the country like its capital city, its neighbouring countries, its continent, etc. Some initial ideas of this nature were explored in Pais (2019).

A.48 German Gender Swap
This transformation replaces the masculine nouns and pronouns with their female counterparts for German sentences from a total of 2226 common German names.

Er → Sie
mein Vater → meine Mutter.

A.49 Grapheme to Phoneme Substitution
This transformation adds noise to a sentence by randomly converting words to their phonemes. Grapheme-to-phoneme substitution is useful in NLP systems operating on speech. An example of grapheme to phoneme substitution is “permit” → P ER0 M IH1 T’.

A.50 Greetings and Farewells
This transformation replaces greetings (e.g. “Hi”, “Howdy”) and farewells (e.g. “See you”, “Good night”) with their synonymous equivalents.

Hey → Hi everyone. It’s nice → Pleased to meet you. How have → are you been?

A.51 Hashtagify
This transformation modifies an input sentence by identifying named entities and other common words and turning them into hashtags, as often used in social media.

A.52 Insert English and French Abbreviations
This transformation replaces in texts some well known English and French words or expressions with (one of) their abbreviations. Many of the abbreviations covered here are quite common on social media platforms, even though some of them are quite generic. This implementation is partly inspired by recent work in Machine Translation (Berard et al., 2019).

A.53 Leet Transformation
Visual perturbations are often used to disguise offensive comments on social media (e.g., ‘!d10t’) or as a distinct writing style (1337 in leet speak) (Eger et al., 2019a), especially common in scenarios like video gaming. Humans are unconsciously robust to such visually similar texts. This perturbation replaces letters with their visually similar “leet” counterparts.

A.54 Lexical Counterfactual Generator
This transformation generates counterfactuals by simply substituting negative words like “not”, “neither” in one sentence of a semantically similar sentence pair. The substituted sentence is then backtranslated in an attempt to correct for grammaticality. This transformation would be useful for tasks like entailment and paraphrase detection.

A.55 Longer Location for NER
This transformation augments data for Named Entity Recognition (NER) tasks by augmenting examples which have a Location Tag. Names of locations are expanded by appending them with cardinal directions like “south”, “N”, “northwest”, etc. The transformation ensures that the tags of the new sentence are accordingly modified.

A.56 Longer Location Names for testing NER
This transformation augments data for Named Entity Recognition (NER) tasks by augmenting examples that

---

21http://download.geonames.org/export/dump/
22https://de.wiktionary.org/wiki/Verzeichnis:Deutsch/Namen
23https://simple.wikipedia.org/wiki/Leet
have a Location (LOC) Tag. Names of location are expanded by inserting random prefix or postfix word(s). The transformation also ensures that the labels of the new tags are accordingly modified.

A.57 Longer Names for NER
This transformation augments data for Named Entity Recognition (NER) tasks by augmenting examples which have a Person Tag. Names of people are expanded by inserting random characters as initials. The transformation also ensures that the labels of the new tags are accordingly modified.

A.58 Lost in Translation
This transformation is a generalization of the Back-Translation transformation to any sequence of languages supported by the Helsinki-NLP OpusMT models (Tiedemann and Thottingal, 2020).

Andrew finally returned the French book the French book I bought last week I bought last week

A.59 Mixed Language Perturbation
Mixed language training has been effective for cross-lingual tasks (Liu et al., 2020), to help generate data for low-resource scenarios (Liu et al., 2021) and for multilingual translation (Fan et al., 2021). Two transformations translate randomly picked words in the text from English to other languages (e.g., German). It can be used to test the robustness of a model in a multilingual setting.

Andrew finally returned the - die Comic book to Chris that I bought last week I bought last week

A.60 Mix transliteration
This transformation transliterates randomly picked words from the input sentence (of given source language script) to a target language script. It can be used to train/test multilingual models to improve/evaluate their ability to understand complete or partially transliterated text.

A.61 MR Value Replacement
This perturbation adds noise to a key-value meaning representation (MR) (and its corresponding sentence) by randomly substituting values/words with their synonyms (or related words). This transformation uses a simple strategy to align values of a MR and tokens in the corresponding sentence inspired by how synonyms are substituted for tasks like machine translation (Fadaee et al., 2017). This way, there could be some problems in complex sentences. Besides, the transformation might introduce non-grammatical segments.

A.62 Multilingual Back Translation
This transformation translates a given sentence from a given language into a pivot language and then back to the original language. This transformation is a simple paraphraser that works on 100 different languages. Back Translation has been quite popular now and has been a quick way to augment (Li and Specia, 2019; Sugiyama and Yoshinaga, 2019; Fan et al., 2020).

Being honest - Honesty should be one of our most important character traits - characteristics

A.63 Multilingual Dictionary Based Code Switch
This transformation generates multi-lingual code-switching data to fine-tune encoders of large language models (Qin et al., 2020; Tan and Joty, 2021; Wang et al., 2019b) by making use of bilingual dictionaries of MUSE (Lample et al., 2018).

A.64 Multilingual Lexicon Perturbation
This perturbation helps to creates code-mixed sentences for both high-resource and low-resource languages by randomly translating words with a specified probability from any supported languages (e.g., English) to other supported languages (e.g., Chinese) by using a multilingual lexicon. Thus, it can be used to generate code-mixed training data to improve models for multilingual and cross-lingual settings. As of now 100 languages are supported and 3000 common English words listed on ef.com are supported. The lexicon implementation is also 160x faster than its model based counterpart.

A.65 Causal Negation & Strengthening
This transformation is targeted at augmenting Causal Relations in text and adapts the code from the paper Causal Augmentation for Causal Sentence Classification (Tan et al., 2021a). There are two operations: 1. Causal Negation: Negative words like "not, no, did not" are introduced into sentences to unlink the causal relation. 2. Causal Strengthening: Causal meaning is strengthened by converting weaker modal words

into stronger ones like “may” to “will” to assert causal strength.

The implementation provides users with the option to amend causal meaning automatically from the root word of the sentence, or by explicitly highlighting the index of the word they wish to amend. Additionally, we include WordNet (Miller, 1998) synonyms and tense matching to allow for more natural augmentations.

The rs7044343 polymorphism could be involved in regulating the production of IL-33.

A.66 Question Rephrasing transformation

This implementation rephrases questions for sentence tasks by using the T5 model used in A.75 for Question Answering tasks.

A.67 English Noun Compound Paraphraser [N+N]

This transformation replaces two-word noun compounds with a paraphrase, based on the compound paraphrase dataset from SemEval 2013 Task 4 (Hendrickx et al., 2013). It currently only works for English. Any two-word compound that appears in a dataset of noun compound paraphrases will be replaced by a paraphrase. If more than one two-word compound appears, then all combinations of compound paraphrases (including no paraphrase at all) will be returned. For example, the paraphrases of “club house” include “house for club activities”, “house for club members”, “house in which a club meets”, etc. We start with replacing paraphrases with the highest score (the specified frequency in the annotated dataset), and paraphrases with the same score (ties) are sorted randomly. This transformation currently only checks for noun compounds from Hendrickx et al. (2013) and therefore has low coverage. To improve it, other datasets could be added, e.g., from Ponkiya et al. (2018) or Lauer (1995). To attain even wider-coverage (at the expense of lower precision), machine learning approaches such as Shwartz and Dagan (2018) or Porziya et al. (2020) could be considered. In addition, some of the the paraphrases in Hendrickx et al. (2013) sound a little odd (e.g., “blood cell” -> “cell of blood”) and may not fit well in context.

A.68 Number to Word

This transformation acts like a perturbation to improve robustness on processing numerical values. The perturbed sentence contains the same information as the initial sentence but with a different representation of numbers.

A.69 Numeric to Word

This transformation translates numbers in numeric form to their textual representations. This includes general numbers, long numbers, basic math characters, currency, date, time, phone numbers, etc.

A.70 OCR Perturbation

This transformation directly induces Optical Character Recognition (OCR) errors into the input text. It renders the input sentence as an image and recognizes the rendered text using the OCR engine Tesseract 4 (Smith, 2007). It works with text in English, French, Spanish, and German. The implementation follows previous work by Namysl et al. (2021).

A.71 Add Noun Definition

This transformation appends noun definitions onto the original nouns in a sentence. Definitions of nouns are collected from Wikidata.

A.72 Pig Latin Cipher

This transformation translates the original text into pig latin. Pig Latin is a well-known deterministic transformation of English words, and can be viewed as a cipher which can be deciphered by a human with relative ease. The resulting sentences are completely unlike examples typically used in language model training. As such, this augmentation change the input into inputs which are difficult for a language model to interpret, while being relatively easy for a human to interpret.

A.73 Pinyin Chinese Character Transcription

This transformation transcribes Chinese characters into their Mandarin pronunciation using the Pinyin romanization scheme. The Character-to-Pinyin converter at the core of this transformation is a neural model by Park and Lee (2020).

A.74 SRL Argument Exchange

This perturbation adds noise to all types of English text sources (sentence, paragraph, etc.) proportional to the number of arguments identified by SRL BERT (Shi and Lin, 2019b). Different rules are applied to deterministically modify the sentence in a meaning-preserving manner. Rules look as follows: if ARGUMENT-LOC and ARGUMENT-TMP both present, exchange them.

25https://www.wikidata.org/wiki/Wikidata:Main_Page
Example: [ARG0: Alex] [V: left] [ARG2: for Delhi] [ARGM-COM: with his wife] [ARGM-TMP: at 5 pm] . → Alex left for Delhi at 5 pm with his wife.

The transformation relies on propbank annotations (Bonial et al., 2012; Kingsbury and Palmer, 2002; Palmer et al., 2005; Gildea and Palmer, 2002).

A.75 ProtAugment Diverse Paraphrasing

This transformation utilizes the ProtAugment method by Dopierre et al. (2021). The paraphrase generation model is a BART model (Lewis et al., 2020), finetuned on the paraphrase generation task using 3 datasets: Google-PAWS (Zhang et al., 2019b), MSR (Dolan and Brockett, 2005), Quora26.

When paraphrasing a sentence, the transformation uses Diverse Beam Search (Vijayakumar et al., 2016) to generate diverse outputs. The diversity penalty term is by default set to 0.5 but can be set to custom values. Additionally, the transformation can use the following generation constraints: (1) A fraction of the words in the input sentence are forbidden in the paraphrase (default 0.7). (2) All bi-grams in the input sentence are forbidden in the paraphrase. This means the paraphrase cannot contain any bi-gram that are in the input sentence. This constraint enforces the paraphrase generation model to change the sentence structure.

A.76 Punctuation

This transformation removes/adds punctuation from an English sentence. This transformation was first introduced by Mille et al. (2021) and used as an example implementation for NL-Augmenter.

A.77 Question-Question Paraphraser for QA

This transformation creates new QA pairs by generating question paraphrases from a T5 model fine-tuned on Quora Question pairs 27. Generated questions can have a very different surface form from the original question making it a strong paraphrase generator. A T5 model (Raffel et al., 2019; Wolf et al., 2020) fine tuned 28 on the Quora Question Pairs dataset was being used to generate question paraphrases. This transformation would benefit Question Answering, Question Generation as well as other tasks which could indirectly benefit eg. for dialog tasks (Shrivastava et al., 2021; Dhole, 2020).

A.78 Question in CAPS

This transformation upper-cases the context of a question answering example. It also adds upper-cased versions of the original answers to the set of acceptable model responses.

A.79 Random Word Deletion

This transformation randomly removes a word with a given probability p (by default 0.25). The transformation relies on whitespace tokenization and thus only works for English and other languages that are segmented via whitespace. Due to the destructive nature of the transformation, it is likely that the meaning of a sequence may be changed as a result of the change. A similar transformation was suggested by Wei and Zou (2019). Word dropout (Goldberg, 2017) has been common to help models understand unknown words encountered during evaluation by exposing them to this unknown-word condition during training itself.

A.80 Random Upper-Case Transformation

This transformation adds noise to all types of text sources (sentence, paragraph, etc.) by randomly adding upper cased letters. With a default probably of 0.1, each character in a sequence is upper-cased. This transformation does not rely on a tokenizer and thus works with all languages that have upper and lower-case letters. One limitation of this transformation is that it will not affect a tokenizer that does lower case for all input. A similar transformation was suggested by Wei and Zou (2019). Further improvement of this transformation exists by potentially relying on extreme value theory (Jalalzai et al., 2020).

A.81 Double Context QA

This transformation repeats the context of a question answering example. This should not change the result in any way.

A.82 Replace Abbreviations and Acronyms

This transformation changes abbreviations and acronyms appearing in an English text to their expanded form and respectively, changes expanded abbreviations and acronyms appearing in a text to their shorter form. For example, “send this file asap to human resources” might be changed to “send this file

https://quoradata.quora.com/First-Quora-Dataset-Release-Question-Pairs
27Quora Question Pairs
28https://huggingface.co/ramsrigoutham/t5_paraphraser

Northern European Journal of Language Technology
as soon as possible to HR”. The list of abbreviations and acronyms used in this transformation where manually gathered focusing on common abbreviations present in business communications. When abbreviation are context-dependent or highly specific, the induced change may change the meaning of a text, or an abbreviation may not be available in the lookup. The transformation was first introduced by Regina et al. (2020).

A.83 Replace Financial Amounts
This transformation replaces financial amounts throughout a text with the same value in a different currency. The replacement changes the amount, the writing format as well as the currency of the financial amount. For example, the sentence “I owe Fred 20 and I need 10 for the bus.” might be changed to “I owe Fred 2,906.37 Yen and I need 1,453.19 Yen for the bus.” The transformation was first introduced by Regina et al. (2020).

A.84 Replace Numerical Values
This transformation looks for numerical values in an English text and replaces it with another random value of the same cardinality. For example, “6.9” may be replaced by “4.2”, or “333” by “789”. The transformation was first introduced by Mille et al. (2021).

A.85 Replace Spelling
This transformation adds noise to all types of English text sources (sentence, paragraph, etc.) using corpora of common spelling errors introduced by Deorowicz and Ciura (2005). Each word with a common misspelling is replaced by the version with mistake with a probability $p$ which by default is set to $0.2$.

A.86 Replace nouns with hyponyms or hypernyms
This transformation replaces common nouns with other related words that are either hyponyms or hypernyms. Hyponyms of a word are more specific in meaning (such as a sub-class of the word), eg: ‘spoon’ is a hyponym of ‘cutlery’. Hypernyms are related words with a broader meaning (such as a generic category /super-class of the word), eg: ‘colour’ is a hypernym of ‘red’. Not every word will have a hypernym or hyponym.

A.87 Sampled Sentence Additions
This transformation adds generated sentence to all types of English text sources (sentence, paragraph, etc.) by passing the input text to a GPT-2 model (Radford et al., 2019). By default, GPT-XL is used, together with the prompt “paraphrase:” appended to the original text, after which up to 75 tokens are sampled. Since the additional text is sampled from a model, the model may introduce harmful language or generate text that contradicts the earlier text or changes its meaning. The idea to sample one or more additional sentences was first introduced by Jia and Liang (2017a).

A.88 Sentence Reordering
This perturbation adds noise to all types of text sources (paragraph, document, etc.) by randomly shuffling the order of sentences in the input text (Lewis et al., 2020). Sentences are first partially decontextualized by resolving coreference (Lee et al., 2018). This transformation is limited to input text that has more than one sentence. There are still cases where coreference can not be enough for decontextualization. For example, there could be occurences of ellipsis as demonstrated by Gangal et al. (2021) or events could be mentioned in a narrative style which makes it difficult to perform re-ordering or shuffling (Kočiský et al., 2018) while keeping the context of the discourse intact.

A.89 Emoji Addition for Sentiment Data
This transformation adds positive emojis and smileys to positive sentiment data and negative emojis to negative sentiment data. For non-labelled data, it adds neutral smileys.

A.90 Shuffle Within Segments
In this transformation, a token sequence, for example BIO-tagged, is split into coherent segments. Thus, each segment corresponds to either a mention or a sequence of out-of-mention tokens. For example, a sentence “She did not complain of headache or any other neurological symptoms.” with tags O O O O O B-problem O B-problem I-problem I-problem I-problem O is split into five segments: [She did not complain of], [headache], [or], [any other neurological symptoms], []. Then for each segment, a binomial distribution ($p=0.5$) is used to decide whether it should be shuffled. If yes, the order of the tokens within the segment is shuffled while the label order is kept unchanged. This transformation is inspired by Dai and Adel (2020).

A.91 Simple Ciphers
This transformation modifies the text in ways that a human could rapidly decipher, but which make the input sequences almost completely unlike typical input sequences which are used during language model training. This transformation includes the following text...
modifications: double the characters, double the words, add spaces between the characters, reverse all characters in the text, reverse the characters within each word, reverse the order of the words in the text, substitute homoglyphs, rot13 cipher.

A.92 Slangificator
This transformation replaces some of the words (in particular, nouns, adjectives, and adverbs) of an English text with their corresponding slang. The replacement is done with the subset of the "Dictionary of English Slang & Colloquialisms". The amount of replacement is proportional to the corresponding probabilities of replacement (by default, 0.5 for nouns, adjectives, and adverbs each).

A.93 Spanish Gender Swap
This transformation changes the gender of all animate entities (mostly referring to people, and some animals) in a given Spanish sentence from masculine to feminine. This includes masculine nouns with feminine equivalents (e.g., doctor doctora), nouns with a common gender ("sustantivos comunes en cuanto al género", e.g., el violinista la violinista), personal pronouns, and (optionally) given names often used with a given gender (e.g., Pedro Alicia). Epicene nouns are excluded. In addition, the gender of adjectives, determiners, pronouns and participles are modified in order to maintain the grammatical agreement.

A.94 Speech Disfluency Perturbation
This perturbation randomly inserts speech disfluencies in the form of filler words into English texts. With a given probability (0.2 by default), a speech disfluency is inserted between words. The default disfluencies are "um", "uh", "erm", "ah", and "er". At least one filler word is always inserted by this transformation.

A.95 Paraphrasing through Style Transfer
This transformation provides a range of possible styles of writing English language. The following styles can be chosen:

- Shakespeare - Trained on written works by Shakespeare.
- Switchboard - Trained on a collection of conversational speech transcripts.
- Tweets - Trained on 5.2M English tweets.

- Bible - Trained on texts from the Bible.
- Romantic poetry - Trained on romantic poetry.
- Basic - A light, basic paraphraser with no specific style.

The transformation follows the models and formulations by Krishna et al. (2020).

A.96 Subject Object Switch
This transformation switches the subject and object of English sentences to generate new sentences with a very high surface similarity but very different meaning. This can be used, for example, for augmenting data for models that assess Semantic Similarity.

A.97 Sentence Summarization
This transformation compresses English sentences by extracting subjects, verbs, and objects of the sentence. It also retains any negations. For example, "Stillwater is not a 2010 American live-action/animated dark fantasy adventure film" turns into "Stillwater is film". Zhang et al. (2021) used a similar idea to this transformation.

A.98 Suspecting Paraphraser for QA
This paraphraser transforms a yes/no question into a declarative sentence with a question tag, which helps to add more question specific informality to the dataset. Example: "Did the American National Shipment company really break its own fleet?" -> "The American National Shipment company really broke its own fleet, didn’t it".

A.99 Swap Characters Perturbation
This perturbation randomly swaps two adjacent characters in a sentence or a paragraph with a default probability (Zhang et al., 2019a).

A.100 Synonym Insertion
This perturbation adds noise to all types of text sources (sentence, paragraph, etc.) by randomly inserting synonyms of randomly selected words excluding punctuations and stopwords (Marivate and Sefara, 2020).

A.101 Synonym Substitution
This perturbation randomly substitutes some words in an English text with their WordNet (Miller, 1998) synonyms.

A.102 Syntactically Diverse Paraphrasing using Sow Reap models

This transformation is capable of generating multiple syntactically diverse paraphrases for a given sentence based on the work of Goyal and Durrett (2020). The model paraphrases inputs using a two step framework: 1) SOW (Source Order reWriting): This step enumerates multiple feasible syntactic transformations of the input sentence. 2) REAP (REarrangement Aware Paraphrasing): This step conditions on the multiple reorderings/rearrangements produced by SOW and outputs diverse paraphrases corresponding to these reorderings. The transformation is designed to work only on single-sentence inputs. Multi-sentence inputs result in an empty string/no transformation. The model are trained on the ParaNMT-50M dataset (Wieting and Gimpel, 2017; Wieting et al., 2017), which can be argued to be a bit noisy.

A.103 Subsequence Substitution for Sequence Tagging

This transformation performs same-label subsequence substitution for the task of sequence tagging, which replaces a subsequence of the input tokens with another one that has the same sequence of tags (Shi et al., 2021). This is done as follows: (1) Draw a subsequence A from the input (tokens, tags) tuple. (2) Draw a subsequence B within the whole dataset, with the same tag subsequence. (3) Substitute A with B in the input example.

A.104 Change English Tense

This transformation converts English sentences from one tense to the other, for example simple present to simple past. This transformation was introduced by Logeswaran et al. (2018).

A.105 Token Replacement Based on Lookup Tables

This transformation replaces input tokens with their perturbed versions sampled from a given lookup table of replacement candidates. Lookup tables containing OCR errors and misspellings from prior work are given as examples. Thus, by default, the transformation induces plausible OCR errors and human typos to the input sentence.

The transformation is an adapted and improved version of the lookup table-based noise induction method from Namysl et al. (2020). The OCR lookup table is from Namysl et al. (2021) and the misspellings from Piktus et al. (2019).

A.106 Transformer Fill

This perturbation replaces words based on recommendations from a masked language model. The transformation can limit replacements to certain POS tags (all enabled by default). Many previous papers have used this technique for data augmentation (Ribeiro et al., 2020; Li et al., 2020b, inter alia).

A.107 Underscore Trick

This perturbation adds noise to the text sources like sentence, paragraph, etc. This transformation acts like a perturbation to test robustness. It replaces some random spaces with underscores (or even other selected symbols). This perturbation would benefit all tasks which have a sentence/paragraph/document as input like text classification and text generation, especially on tasks related to understanding/generating scripts.

A.108 Unit converter

This transformation converts length and weight measures to different units (e.g., kilometers to miles) picking at random the new unit but converting accurately the quantity. The transformation conserves the format of the original quantity: “100 pounds” is converted to “1600 ounces” but “one-hundred pounds” is converted to “one thousand, six hundred ounces”. Generated transformations display high similarity to the source sentences.

A.109 Urban Thesaurus Swap

This perturbation randomly picks nouns from the input source to convert to related terms drawn from the Urban Dictionary 31 resource. It can be applied to an input text to produce semantically-similar output texts in order to generate more robust test sets. We first select nouns at random, then query the Urban Thesaurus website 32 to obtain a list of related terms to swap in (Wilson et al., 2020).

A.110 Use Acronyms

This transformation changes groups of words for their equivalent acronyms. It’s a simple substitution of groups of words for their acronyms. It helps to increase the size of the dataset as well as improving the understanding of acronyms of models trained on data augmented with this transformation. This transformation works to increase the data for any task that has input texts. It is specially interesting for tasks on semantic similarity, where models should be aware of the

---

31https://www.urbandictionary.com/
32https://urbanthesaurus.org/
equivalence between a set of words and their acronym. The quality of the transformation depends on the list of acronyms. As of now, this list was scraped from wikipedia’s List of Acronyms and naively filtered, which leaves space for improvement.

A.111 Visual Attack Letter
This perturbation replaces letters with visually similar, but different, letters. Every letter was embedded into 576-dimensions. The nearest neighbors are obtained through cosine distance. To obtain the embeddings the letter was resized into a 24x24 image, then flattened and scaled. This follows the Image Based Character Embedding (ICES) \citep{eger2019neural}.

The top neighbors from each letter are chosen. Some were removed by judgment (e.g. the nearest neighbors for ‘v’ are many variations of the letter ‘y’) which did not qualify from the image embedding \citep{eger2019neural}.

A.112 Weekday Month Abbreviation
This transformation abbreviates or expands the names of months and weekdays, e.g. Mon. -> Monday. Generated transformations display high similarity to the source sentences and does not alter the meaning and the semantic of the original texts. It does not abbreviate plural names, e.g. Sundays, and does not influence texts without names of weekdays or months.

A.113 Whitespace Perturbation
This perturbation adds noise to text by randomly removing or adding whitespaces.

A.114 Context Noise for QA
This transformation chooses a set of words at random from the context and the question and forms a sentence out of them. The sentence is then prepended or appended to the context to create a new QA pair. The transformation is inspired by the the AddAny method described in Adversarial SQUAD \citep{jia-liang-2017-adversarial}. However, instead of probing the model to generate adversaries, random words from the context and the question are simply selected and joined together into a sentence, ignoring grammaticality. The transformation attempts to create novel QA pairs assuming that the introduction of random words to the context is less likely to change the answer choice to an asked question.

A.115 Writing System Replacement
This transformation replaces the writing system of the input with another writing system. We use CJK Unified Ideographs as the source of characters for the generated writing systems. The transformation would benefit text classification tasks, especially in the cases where the input writing system is undeciphered.

A.116 Yes-No Question Perturbation
This transformation turns English non-compound statements into yes-no questions. The generated questions can be answered by the statements that were used to generate them. The text is left largely unchanged other than the fronted/modified/added auxiliaries and be-verbs.

The transformation works by getting dependency parse and POS tags from a machine learning model and applying human-engineered, rule-based transformations to those parses/tags. This transformation would particularly benefit question-answering and question-generation tasks, as well as providing surplus legal text for language modeling and masked language modeling.

A.117 Yoda Transformation
This perturbation modifies sentences to flip the clauses such that it reads like “Yoda Speak”. For example, “Much to learn, you still have”. This form of construction is sometimes called ”XSV”, where “the X being a stand-in for whatever chunk of the sentence goes with the verb”, and appears very rarely in English normally. The rarity of this construction in ordinary language makes it particularly well suited for NL augmentation and serves as a relatively easy but potentially powerful test of robustness.

B Filters
The following is the list of all submitted filters to NL-Augmenter. Filters are used to filter data and create subpopulations of given inputs, according to features such as input complexity, input size, etc. Therefore, the output of a filter is a boolean value, indicating that whether the input meet the filter criterion. We discuss the implementations of each filter alongwith their limitations. The title of each filter subsection is clickable and redirects to the actual python implementation.

B.1 Code-Mixing Filter
This filter identifies whether the input text is code-mixed. It checks that there is at least one sentence in

\footnote{https://en.wikipedia.org/wiki/Lists_of_acronyms}

\footnote{https://en.wikipedia.org/wiki/CJK_Unified_Ideographs}
the text where there are tokens representing at least \( k \) unique languages (with at least a 'threshold' level of confidence that the token is of that language). It is useful for collecting code-mixed data to test the model’s performance on multilingual tasks. The filter rely on ftlid\(^{35}\) for language detection, therefore, this filter might be limited by the performance of the language detection tool.

(containing code-mixing) Yo estaba con Esteban yesterday, he was telling me about lo que su esposa vio en los Estados Unidos. -True

B.2 Diacritics Filter
This filter checks whether any character in the sentence has a diacritic. It can be used to create splits of the dataset where the sentences have diacritics. Accent characters are typically among the rarer characters and checking the model performance on such a split might help investigate model robustness.

(containing diacritics) She looked east an she looked west. -True

B.3 Encoding Filter
This filter filters examples which contain characters outside a given encoding. It can be used to find examples containing e.g. non-ASCII Unicode characters. Filtering out and testing examples that contain these characters can provide feedback on how to improve the models accordingly, since most models are trained with plain English text, which contains mostly ASCII characters. Sometimes non-ASCII character are even explicitly stripped away.

(containing non-ASCII characters) That souvenir sure was expensive at 60€.. or was it 60? -True

B.4 Englishness Filter
This filter identifies texts that contain uniquely British spellings, vocabulary, or slang. The filter uses a vocabulary of common British words/phrases and checks the number of occurrence of British words in the given texts. The text is selected if the number exceeds a pre-defined threshold.

(containing British spellings) Colour is an attribute of light that is perceived by the human eye. -True

B.5 Gender Bias Filter
This filter filters a text corpus to measure gender fairness with respect to a female gender representation. It supports four languages (i.e. English, French, Polish and Russian) and can be used to define whether the female gender is sufficiently represented in a tested subset of sentences. The filter uses a list of lexicals, which includes filter categories such as personal pronouns, words defining the relation, titles and names, corresponding to the female and male genders accordingly.

(texts with unbalanced representation) "He went home", "He drives a car", "She has returned" -True

B.6 Group Inequity Filter
This is a bilingual filter (for English and French languages), which helps to discover potential group inequity issues in the text corpus. It is a topic agnostic filter which accepts user-defined parameters, consisting of keywords inherent to minor group (which potentially might suffer from the discrimination), major group, minor factor and major factor. The filter first flags the sentences as belonging to the minor, and the major groups, and then, the sentences from each of the groups are used to define the intersection with both factors. The filter then compares whether the percentage of major factors exceeds that of the minor factors to determine if the sentences have group inequity issues.

(containing group inequity issues) "He is a doctor", "She is a nurse", "She works at the hospital" -True

B.7 Keyword Filter
This is a simple filter, which filters examples based on a pre-defined set of keywords. It can be useful in creating splits for a specific domain.

(containing keyword "at") Andrew played cricket in India -True

B.8 Language Filter
This filter selects texts that match any of a given set of ISO 639-1 language codes (the default language being English). Language matching is performed using a pre-trained langid.py model instance. The model provides normalized confidence scores. A minimum threshold score needs to be set, and all sentences with confidence scores above this threshold are accepted by the filter.

(is English texts) Mein Luftkissenfahrzeug ist voller Aale -False

B.9 Length Filter
This filter filters data with the input text length matching a specified threshold. It can be useful in creating data with different length distributions.

(containing more than 3 words) Andrew played cricket in India -True
B.10 Named-entity-count Filter
This filter filters data where the number of Named Entities in the input match a specified threshold (based on the supported conditions).

(containing more than 1 named entity) Novak Djokovic is the greatest tennis player of all time. - True

B.11 Numeric Filter
This filter filters example which contain a numeric value. In the tasks like textual entailment, question answering etc., a quantity (number) could directly affect the final label/response. This filter can be used to create splits to measure the performance separately on texts containing numeric values.

(containing numbers in texts) John bought a car worth dollar twenty five thousand. - True

B.12 Oscillatory Hallucinations Filter
This filter is designed to operate in text generation systems' outputs, with the purpose of extracting oscillatory hallucinations. Oscillatory hallucinations are one class of hallucinations characterized by repeating bigram structure in the output (Raunak et al., 2021). Typically, these behaviors are observed in models trained on noisy corpora. The filter counts the frequency of bigrams in both source and target texts, and compare the frequency difference with a pre-set threshold to determine whether the texts includes oscillatory hallucinations.

(containing hallucinations in target texts) Source: "Community, European Parliament common regional policy, Mediterranean region", Target: "Arbeitsbedingungen, berufliche Bildung, berufliche Bildung, berufliche Bildung" - True

B.13 Polarity Filter
This filter filters a transformed text if it does not retain the same polarity as an original text. This filter helps not to distort training data during augmentation for sentiment analysis-related tasks. While generating new data for a sentiment analysis task, it is important to make sure that generated data is labelled correctly.

(texts retaining polarity) "Hotel is terrible", "Hotel is great" - False

B.14 Quantitative Question Filter
This is a simple rule-based filter that can be used to identify quantitative questions. It can help to analyse models’ performance on questions which require numerical understanding. It is also useful to study possible biases in question generation.

(being quantitative question) How long does the journey take? - True

B.15 Question type filter
This filter helps identify the question category of a question answering example based on the question word or the named entity type of the answer. Knowledge of the question type can help in the development of question answering systems (Parikh et al., 2019) as well as for assessing performance on individual splits.

(being where question) Where is Delhi located? - True

B.16 Repetitions Filter
This filter finds texts with repetitions with simple heuristic rules. It might be helpful in finding repetitions that frequently occur in the spoken language data.

(containing repetitions in texts) I I want to sleep - True

B.17 Phonetic Match Filter
This filter selects texts that contain matching entries to a list of supplied keywords. It first transform the input sentence and the keywords into phonetic units and then compare whether the two phonetic unit sets have overlap.

(containing homophones of keyword "trombone") I left my trombno on the train - True

B.18 Special Casing Filter
This filter checks if the input sentence has a special casing, i.e. the string is either all lowercased, all uppercased or has title casing. It might be useful for creating splits that contain texts with unusual casing, e.g. misspellings.

(text being uppercased/lowercased/titlecased) let’s go to chipotle - True

B.19 Speech-Tag Filter
This filter filters an example text based on a set of speech tags and identifies whether the count of selected POS tags meet the pre-defined conditions (e.g. above the threshold).

(contains 1 verb and 2 numbers in texts) It all happened between November 2007 and November 2008. - True

B.20 Token-Amount filter
This filter filters an example text based on whether certain keywords are present in a specified amount.
Andrew played cricket in a soccer stadium in India at 9pm - True

B.21 Toxicity Filter

This filter filters an example text which has a toxicity value matching a particular threshold. It uses a pre-trained toxicity detector, which can provide 7 toxicity scores. All the 7 types of toxicity scores can be used as criteria for the filtering.

(text being toxic) I disagree. It is not supposed to work that way. - False

B.22 Universal Bias Filter

This filter works the same way as the Gender Bias Filter, but measures balance of representation for more categories (religion, race, ethnicity, gender, sexual orientation, age, appearance, disability, experience, education, economic status). The lexical seeds representing these categories are currently available in English only, however the pool of languages can be extended by a simple addition of the lexical seeds in a desired language to the lexicals.json file.

(texts being biased) "He is going to make a cake.", "She is going to program", "Nobody likes washing dishes", "She agreed to help him" - False

B.23 Yes/no question filter

This filter allows to select questions that can be correctly answered with either ‘yes’ or ‘no’. Since it is rule-based, the limitation of this filter is that questions that are ambiguous might not be recognized.

(text being yes/no question) Wasn’t she angry when you told her about the accident? - True

C Review criteria for submission evaluation

Figure 3 shows the detailed review criteria used for evaluating the transformation and filters submissions.
Table 7: Results of the robustness evaluation from the perspective of the **General purpose** criterion ($\#_{All}$ = Total number of tags, $\#_{Evl}$ Total number of evaluations collected, $R_T$ = Transformation rate, $Var_S$ = Score variation)

Correctness: Transformations must be valid Python code and must pass tests.

Interface: Participants should ensure that they use the correct interface. The complete list is mentioned here. E.g., for tasks like machine translation, a transformation which changes the value of a named entity (Andrew->Jason) might need parallel changes in the output too. And hence, it might be more appropriate to use SentenceAndTargetOperation or SentenceAndTargetOperation rather than SentenceOperation. Similarly, if a transformation changes the label of a sentence, the interface's generate method should take as input the label too - e.g., if your transformation reverses the sentiment. SentenceAndTargetOperation would be more appropriate than SentenceOperation. If you wish to add transformations for input formats other than those specified, you should add an interface here.

Applicable Tasks & Keywords: We understand that transformations can vary across tasks and as a single transformation can work for multiple tasks. Hence all the tasks where the transformation is applicable should be specified in the list “tasks”. The list of tasks has been specified here. The relevant keywords for the transformation should also be specified.

class ButterFingersPerturbation(SentenceOperation):
    tasks = [TaskType.TEXT_CLASSIFICATION, TaskType.TEXT_TO_TEXT_GENERATION, TaskType.TEXT_TOKENIZATION]
    Languages = ['en']
    keywords = ['morphological', 'noise', 'rule-based', 'high-coverage', 'high-precision']

Specificity: While this is not a necessary criterion, it is highly encouraged to have a specific transformation. E.g., a perturbation which changes gendered pronouns could give insights about gender bias in models.

Novelty: Your transformation must improve the coverage of NL-Augmenter in a meaningful way. The idea behind your transformation need not be novel, but its contribution to the library must be different from the contributions of earlier submissions. If you are unsure if your idea would constitute a new contribution, please email the organizers at nl-augmentor@googlegroups.com and we are happy to help.

Adding New Libraries: We welcome addition of libraries which are light and can be installed via pip. Every library should specify the version number associated and be added in a new requirements.txt file in the transformation's own folder. However, we discourage the use of heavy libraries for a few lines of code which could be manually written instead. Please ensure that all libraries have MIT, Apache 2, BSD, or other permissive license. GPL-licensed libraries are not approved for NL-Augmenter. If you are unsure, please email the organizers at nl-augmentor@googlegroups.com.

Description: The README.md file should clearly explain what the transformation is attempting to generate as well as the importance of that transformation for the specified tasks. Here is a sample README.

Data and code source: The README.md file should have a subsection titled "Data and code provison", which should describe where data or code came from, or that it was fully created by the author. This section should also disclose the license that any external data or code is released under.

Paraphrasers and Data Augmenters: Besides perturbations, we welcome transformation methods that act like paraphrasers and data augmenters. For non-deterministic approaches, we encourage you to specify metrics which can provide an estimate of the generation quality. We prefer high precision transformation generators over low accuracy ones. And hence it’s okay if your transformation selectively generates.

Test Cases: We recommend you to add at least 5 examples in the file test.json as test cases for every added transformation. These examples serve as test cases and provide reviewers a sample of your transformation’s output. The format of test.json can be borrowed from the sample transformations here. A good set of test cases would include good as well as bad generation. Addition of the test cases is not mandatory but is encouraged.

Evaluating Robustness: To make a stronger PR, a transformation’s potential to act as a robustness tool should be tested via executing evaluate.py and the corresponding performance should be mentioned in the README. Evaluation should only be skipped in case there is no support in the evaluation engine.

Languages other than English: We strongly encourage multilingual perturbations. All applicable languages should be specified in the list of languages.

Decent Programming Practice: We recommend adding docstrings to help others follow your code with ease. Check the PEP 257 Docstring Conventions to get an overview. If you are using jupyter, we suggest you use the common global version like this.

All of the above criteria extend to tests too.

Figure 3: Participants and reviewers were provided with a set of review criteria.
